Stochastic Dominance and Option Pricing in Discrete and Continuous Time: an Alternative Paradigm

By Ioan Mihai Oancea and Stylianos Perrakis

Abstract

This paper examines option pricing in a universe in which it is assumed that markets are incomplete. It derives multiperiod discrete time option bounds based on stochastic dominance considerations for a risk-averse investor holding only the underlying asset, the riskless asset and (possibly) the option for any type of underlying asset distribution. It then considers the limit behavior of these bounds for special categories of such distributions as trading becomes progressively more dense, tending to continuous time. It is shown that these bounds nest as special cases most, if not all, the existing arbitrage-based option pricing models. These include the cases where the underlying asset follows a generalized diffusion, a jump-diffusion process, as well as several stochastic volatility models.

Key words: Option pricing, option bounds, incomplete markets, jump-diffusion processes.

1The authors are, respectively, PhD student and Professor at the John Molson School of Business, Concordia University. Perrakis acknowledges the support of SSHRC, the Social Sciences and Humanities Research Council of Canada.
Introduction

There have now been more than thirty years since the publication of the seminal Black and Scholes (1973) and Merton (1973) studies that established the foundations of modern option pricing theory. The significance of these studies lay as much in the arbitrage valuation methodology that they introduced as in the derived results. The option prices in these studies were derived by the construction of a riskless hedge that was supposed to earn a return equal to the riskless rate of interest. Alternatively, they may be derived by the construction of a portfolio containing the underlying and the riskless assets that replicates the option perfectly in all states of the world. If such a replication is feasible then it can be shown that the price of any contingent claim on the underlying asset is equal to the discounted expected payoff of the claim under a risk neutral transformation of the underlying asset’s return distribution, generally denoted as the $Q$-distribution.\(^2\) It is this arbitrage-based methodology that underlies the overwhelming majority of derivatives pricing studies in modern financial theory.

The arbitrage methodology relies on two fundamental assumptions that cannot be relaxed easily in most applications. These are known as dynamic market completeness and frictionless trading. The former is most often identified with a distribution of the returns of the underlying asset that follows a univariate diffusion process. The latter is generally interpreted as the absence of transaction costs in trading the underlying asset. While there are extensions of the basic arbitrage methodology that can take care of several forms of market incompleteness, there is no satisfactory arbitrage-based approach to option pricing in the presence of transaction costs.\(^3\) Even for the cases of market incompleteness, the proposed option pricing models are specific to each type of underlying distribution, without any unifying theory; they thus require the identification of the type of underlying asset distribution before deriving a price for the option.\(^4\)

In this paper we examine an alternative class of option pricing models that have existed for several years but have received little attention in mainstream financial research.\(^5\) These models were initially designed to take into account market incompleteness, but they have been recently extended to incorporate proportional transaction costs in trading the underlying asset.\(^6\) Under their existing form they are applicable to underlying asset whose returns distributions are independent and identically distributed (iid) between

---

3 See Merton (1989), and Soner et al (1996).

4 Mixed jump-diffusion processes, GARCH processes and stochastic volatility are three examples of market incompleteness that have appeared in the literature. In such incompleteness cases the $Q$-distribution is not uniquely defined by arbitrage methods alone and additional assumptions are needed to derive it. See Merton (1976), Hull and White (1987), Amin and Ng (1993), Amin (1993), and Duan (1995) for some examples.

5 This class of models was introduced by Perrakis and Ryan (1984) and extended by Levy (1985) and Ritchken (1985) in a single period context. The multiperiod extension was done in Perrakis (1986, 1988) and Ritchken and Kuo (1988).

successive time periods. Unlike the riskless hedge of the mainstream arbitrage approach, these models rely on stochastically dominating strategies involving portfolios containing the option, the underlying asset and the riskless asset.

In this paper we first extend the models to underlying asset distributions whose returns are Markovian but non-iid. We then show that at least for “plain vanilla” call and put options the results of this stochastic dominance option pricing approach contain as special cases virtually the entire set of results produced by the conventional arbitrage methodology. Furthermore, these results are common to all types of underlying asset distributions, and not only to distributions belonging to a given class. They can thus be used to price options on assets for which the return distribution is known only under the form of a histogram extracted from historically observed values, or where such a distribution has been distorted to incorporate subjective forecasts. Last but not least, since the models’ results are formulated in discrete time and cover continuous time as a limit; they may thus be used to value American, as well as European options.

The results of this stochastic dominance approach to option pricing take the form of two bounds on admissible option prices; an observed market price outside the bounds triggers an expected utility-improving strategy of writing or purchasing the mispriced option. We show that for the basic case of a dynamically complete market without transaction costs, in which the underlying asset follows a generalized Ito process, the two bounds of the stochastic dominance approach converge to a single value, the one corresponding to the arbitrage-derived option price, under all circumstances. This convergence takes place even though the market for the underlying asset is incomplete for any discrete time subdivision of the time to expiration of the option. Since the convergence takes place even when there is no closed-form option price derived from the arbitrage-based approach, the two bounds provide an alternative method of deriving such a price via Monte Carlo simulations of the general form of the equations of the bounds, without making any assumptions on a “risk-neutral process” under which the option is priced.

Next we examine the stochastic dominance approach in cases in which the market is dynamically incomplete. We examine the two main types of market incompleteness that have appeared in the literature, a mixed jump-diffusion process for the distribution of the underlying asset, and a stochastic volatility process for this same distribution. For the mixed jump-diffusion process there are two possible approaches in the earlier studies. Merton (1976) assumes that the risk arising out of the jump process is fully diversifiable and that the amplitude of the jumps is lognormally distributed. He then applies the traditional arbitrage method to derive an option price that is an expectation of Black-Scholes-type expressions. Other studies such as Bates (1991), Amin (1993) and Amin and Ng (1993), use general equilibrium-type arguments, in which the marginal utility of consumption of a representative investor plays the role of a pricing operator; the option price becomes then a function of the investor’s risk aversion parameter. On the other

---

7For instance in the simple Black-Scholes diffusion, as well as in the so-called constant elasticity of variance (CEV) approach, as in Cox and Rubinstein (1985, pp. 361-364).
8A similar equilibrium argument underlies the GARCH option pricing models, first presented in Duan (1995).
hand, the stochastic volatility models handle market incompleteness by specifying, somewhat arbitrarily, a “price” of the volatility risk in order to derive a risk neutral process, a form of the $Q$-distribution that can be used to price contingent claims.\(^9\)

We show in this paper that under mixed jump-diffusion processes the bounds of the stochastic dominance approach converge to two distinct values for any distribution of the jump amplitude. Further, these bounds contain all the values derived by the equilibrium models, including the one corresponding to the Merton (1976) assumption, as well as those of Bates (1991) and Amin (1993). Similarly, the stochastic dominance bounds can be suitably redefined to cover virtually all the stochastic volatility models that have appeared in the literature, with the two bounds converging to a single value whenever volatility risk is assumed fully diversifiable, as in Hull and White (1987).

In the next section we summarize briefly the option bounds derived by the stochastic dominance approach as it has appeared in the literature till now, when the returns of the underlying asset are independent and identically distributed (iid). The extension to a Markovian structure of returns is discussed in section III, while the limiting forms of the bounds when the stock returns follow a general Ito process are shown in section IV. Sections V, VI and VII present the results for mixed jump-diffusions, stochastic volatility and GARCH processes. Section VIII concludes.

1. The Stochastic Dominance Approach

The stochastic dominance results were initially derived in Perrakis and Ryan (1984) by eliminating stochastically dominating strategies in comparing two portfolios. They were extended by considering a single period market equilibrium model in Ritchken (1985), and by second order stochastic dominance (SSD) comparisons of the terminal wealth distributions by Levy (1985). Of these the portfolio comparisons and the market equilibrium (but not the SSD comparisons of terminal wealth) approaches have been extended to multiperiod problems by Perrakis (1986, 1988) and Ritchken and Kuo (1988).\(^{10}\) Here we adopt the formulation of this latter study.

Consider a two period economy with $n$ states of nature at time $T$. There is a stock with price $S_0$ and a bond with price $B_0$ at time 0. The $n$ states are ordered by the stock payoff $s_j$ at option expiration. Thus, the stock pays $s_j$ dollars in state $j$, where $j$ is an index, such that $s_1 \leq s_2 \cdots \leq s_n$. The probabilities of the $n$ states are $p_1, p_2, \ldots, p_n$. The pricing kernel, the state-contingent discount factors, are denoted by $Y_1, \ldots, Y_n$, and it is assumed that $Y_1 \geq Y_2 \geq \cdots \geq Y_n$. The bond pays one dollar in each state. There is also a call option with strike price $K$ and with payoffs $c_T = c_1, c_2, \ldots, c_n$ in the $n$ states of the economy. Then the lower (upper) bounds of the option can be obtained by solving the following

\(^9\) Hull and White (1987) assume that the stochastic volatility risk is diversifiable (the price of volatility risk is zero); while Heston (1993) and Bates (1996) adopt particular forms of that price of risk.

\(^{10}\) Only the portfolio comparisons approach has been extended to cover transactions costs. See Constantinides and Perrakis (2002, 2006).
linear programming problems:

$$\min (\max) \ c_0 = \sum_{j=1}^{n} c_j p_j Y_j$$

subject to:

$$S_0 = \sum_{j=1}^{n} s_j p_j Y_j$$

$$B_0 = \sum_{j=1}^{n} p_j Y_j$$

$$0 \leq p_j \leq 1$$

$$Y_1 \geq Y_2 \geq \ldots \geq Y_n$$

(2.1)

Except for the last one, the remaining constraints of the problem reflect the definition of a no arbitrage market equilibrium and the state-contingent discount factors. The objective of this linear program is the option price, while the first two constraints are the prices of the stock and the bond. The last constraint incorporates a basic assumption of the stochastic dominance approach, the monotonicity of the state contingent discount factors with respect to the stock returns. This assumption is rigorously justified in all cases when both of the following two conditions hold:

a. There exists at least one investor in the economy who holds only the stock and the riskless asset;

b. There is no other trading date from time zero till the expiration of the option.\(^{11}\)

Assumption (a) is a sufficient condition that guarantees the monotonicity of the pricing kernel, which is the normalized marginal utility of the investor holding the stock and the riskless asset.\(^{12}\) If the expected stock return \(\hat{z}_n \equiv (\sum_{j=1}^{n} s_j p_j) / S_0\) is greater than or equal to the riskless return \(R = B_0\), then the investor is always long in the stock and the ordering of the state contingent discount factors shown in (2.1) holds. An option price violating the upper (lower) of the bounds defined by (2.1) triggers a strategy of writing (purchasing) the violating option, which increases expected utility for any risk averse investor.

Assumption (a) may be restrictive for options on individual stocks, but its validity in the case of index options cannot be doubted, given that fact that numerous surveys have shown that a large number of US investors follow indexing strategies in their

\(^{11}\)Grundy (1991) presents an example of a two-period non-recombining binomial tree in which the call payoffs are not monotone non-decreasing with respect to the stock returns; a similar case is also in Cox and Rubinstein (1985, p. 157 footnote 14). It is important to note that the stochastic dominance approach is still valid in its recursive form in those cases, since condition (b) is violated in these examples.

\(^{12}\)The monotonicity of the pricing kernel appears also as a necessary condition in several asset pricing models in which assumption (a) clearly does not hold. See the review monograph by Jackwerth (2004).
investments. Note also that all option pricing models that combine arbitrage with equilibrium-type arguments use a monotone pricing kernel to price the options, which is the only feature arising out of assumption (a) used in deriving the bounds. The ordering of the state contingent discount factors shown in (2.1) is exactly reversed but the analysis still holds if \( \hat{z}_n \leq R \); this case will be examined as an extension.

A key factor in the stochastic dominance approach is the convexity of the option payoffs. Given such convexity, it can be shown that the two problems shown in (2.1) have the following solutions, which can be found with a simple geometric argument presented in Ritchken (1985)

\[
C_0 = \frac{1}{R} \left[ \frac{R - \hat{z}_1}{\hat{z}_n - \hat{z}_1} \hat{c}_1 + \frac{\hat{z}_n - R}{\hat{z}_n - \hat{z}_1} c_1 \right] \\
C_0 = \frac{1}{R} \left[ \frac{R - \hat{z}_{h+1}}{\hat{z}_{h+1} - \hat{z}_h} \hat{c}_{h+1} + \frac{\hat{z}_h - R}{\hat{z}_{h+1} - \hat{z}_h} \hat{c}_h \right]
\]

(2.2)

In (2.2) we denote by \( z_i, i = 1, \ldots, n \), the stock returns \( s_i / S_0 \), and we define the following conditional expectations for \( j = 1, \ldots, n \):

\[
\hat{c}_j = \frac{\sum_{i=i}^{j} c_i P_i}{\sum_{i=i}^{j} P_i} = E \left[ c_T \mid S_T \leq s_j \right] \\
\hat{z}_j = \frac{\sum_{i=i}^{j} z_i P_i}{\sum_{i=i}^{j} P_i} = E \left[ z_T \mid z_T \leq z_j \right]
\]

(2.3)

In the expressions (2.2) \( h \) is a state index such that \( \hat{z}_h \leq R < \hat{z}_{h+1} \). The convexity of the option payoffs implies that the expressions \( \hat{c}_j \) form a convex function of the conditional mean of the asset return \( \hat{z}_j = E[S_T / S_0 \mid S_T / S_0 < z_j] \). The upper bound is a linear combination of the lowest return and the mean return, while the lower bound is a linear combination of the conditional expected returns \( \hat{z}_h \) and \( \hat{z}_{h+1} \). Therefore, the upper bound is a function of all the next period returns, while the lower bound is a function of \( z_1, \ldots, z_{h+1} \).

From the expressions (2.2) it can be easily seen that the two call option bounds are discounted expectations of the option payoff under two risk neutral probability distributions, as in the conventional binomial model. By substituting the conditional expected returns \( j \) in the bounds formulas, the upper bound can be expressed as the expectation of the payoff under the risk neutral probability measure.

---

13 Bogle (2005) reports that in 2004 index funds accounted for about one third of equity fund cash inflows since 2000 and represented about one seventh of equity fund assets.

14 Note that in the binomial model (\( n = 2 \)) the two bounds distributions coincide and define a unique option price; see Perrakis (1986). The stochastic dominance approach is, thus, a generalization of the binomial model.
\[ U_j = \frac{R - \hat{z}_j}{\hat{z}_n - \hat{z}_1} \sum_{k=1}^{h+1} p_k, \quad j = 1, \ldots, h+1, \quad j = 2, \ldots, n \]  \hspace{1cm} (2.4)

The lower bound, on the other hand, is the expectation of the option payoff in states \(1, \ldots, h+1\) under the risk neutral probability measure

\[ L_j = \frac{\hat{z}_j - R}{\hat{z}_n - \hat{z}_1} \sum_{k=1}^{h+1} p_k, \quad j = 1, \ldots, h+1 \]

\[ L_{h+1} = \frac{\hat{z}_j - R}{\hat{z}_n - \hat{z}_1} \sum_{k=1}^{h+1} p_k \]  \hspace{1cm} (2.5)

Under the two probability measures the option bounds become

\[ C(S) = \frac{1}{R} E^U[\max(Sz - K, 0)] \]

\[ C(S) = \frac{1}{R} E^L[\max(Sz - K, 0)] \]  \hspace{1cm} (2.6)

where \(C(S)\) and \(C(S)\) are convex functions.

From these expressions it can be seen that the upper bound distribution is a mixture of the subjective probability distribution \(P(z)\) of the underlying asset return \(z = S_T / S_0\) and a distribution concentrated at \(z_{\min}\), the lowest possible asset return.

\[ U(z) = \begin{cases} P(z) & \text{with probability } \frac{R - z_{\min}}{E(z) - z_{\min}} \\ 1_{z_{\min}} & \text{with probability } \frac{E(z) - R}{E(z) - z_{\min}} \end{cases} \]  \hspace{1cm} (2.7)

This general formula applies both for continuous and discrete distributions of the returns. The weight of the lowest value in this mixture is such that \(U(z)\) is a risk neutral distribution. The transformation shown in (2.7) does not hold for distributions \(P(z)\) with \(z_t = z_{\min} = \min[z] = 0\). In this case, the upper bound becomes

\[ C = \frac{1}{E(z)} E^U[\max(Sz - K, 0)] \]  \hspace{1cm} (2.8)

The upper bound in this case is obtained by discounting the expected option payoff at the expected rate of return of the stock price.

Similarly, the lower bound distribution is a mixture of two truncated multinomial distributions.
\[
\overline{C} = \frac{1}{E(z)} E^P[\max(Sz - K, 0)]
\]

(2.9)

\[
L(z) = \begin{cases} 
P(z | \hat{z} < \hat{z}_h) & \text{with probability} \frac{z_{h+1} - R}{z_{h+1} - z_h} \\
P(z | \hat{z} < \hat{z}_{h+1}) & \text{with probability} \frac{R - z_h}{z_{h+1} - z_h}
\end{cases}
\]

(2.10)

If the underlying asset has a continuous distribution, the probability for computing the lower bound is the truncated distribution

\[
L(z) = P(z | E(z) \leq R)
\]

(2.11)

This distribution is obtained by truncating the given returns distribution till the expected return becomes equal to the riskless rate.

An alternative representation of the bounds that links the stochastic dominance approach to the conventional equilibrium valuation of contingent claims is by taking the expectation with the measure \( P(z) \) of the call payoff multiplied by a stochastic discount factor \( Y^U \) or \( Y^L \) for the upper and lower bounds respectively. In such a case we have

\[
\overline{C}(S) = E[\max(Sz - K, 0)]Y^U
\]

\[
\overline{C}(S) = E[\max(Sz - K, 0)]Y^L
\]

(2.12)

with the factors \( Y^U \) and \( Y^L \) given by the following expressions for continuous distributions \( P(z) \)

\[
Y^U(z) = \frac{1}{R}(1 - Q) + \frac{1}{R}Q \delta(z_{\min})
\]

(2.13)

\[
Y^L(z) = \begin{cases} 
\frac{1}{R} \frac{1}{P(z \leq z_h)} & \text{if} z \leq z_h \\
0 & \text{if} z > z_h
\end{cases}
\]

where \( E(z | z \leq z_h) = R \), \( \delta(\cdot) \) is Dirac's delta and \( Q = \frac{E(z) - R}{E(z) - z_{\min}} \). This representation will also be useful in the multiperiod formulation of the next section.

Last, we present the single period option bounds for the case where \( \hat{z}_n < R \). Although this case is not very relevant in either single period or multiperiod iid returns, it may arise in individual subperiods when the parameters of the return distribution are functions of the stock price at the beginning of the subperiod. It may also arise in the pricing of options on the exchange rate. The expressions for \( \overline{C}(S) \) and \( \underline{C}(S) \) are very similar to (2.2). Instead of (2.3) we now define the conditional expectations
\[
\tilde{c}_j = \frac{\sum_{i=j}^{n} c_i p_i}{\sum_{i=j}^{n} p_i} = E[c_r | s_r \geq s_j] \\
\tilde{z}_j = \frac{\sum_{i=j}^{n} z_i p_i}{\sum_{i=j}^{n} p_i} = E[z_r | z_r \geq z_j]
\]

(2.3)

Then instead of (2.2) we get

\[
C_0 = \frac{1}{R} \begin{bmatrix}
\frac{z_{h+1} - R}{c_{h+1}} - \frac{R - z_h}{c_h}
\end{bmatrix}
\]

(2.2)

\[
\tilde{C}_0 = \frac{1}{R} \begin{bmatrix}
\frac{z_n - R}{c_1} + \frac{R - z_1}{c_n}
\end{bmatrix}
\]

Here again the two states \(z_h\) and \(z_{h+1}\) are defined from the relation \(z_h \leq R \leq z_{h+1}\). For a continuous return distribution \(P(z)\) the risk neutral distributions \(U(z)\) and \(L(z)\) of the upper and lower bounds respectively become, instead of (2.7) and (2.10)

\[
U(z) = \begin{cases}
P(z) & \text{with probability } \frac{z_{\max} - R}{z_{\max} - E(z)} \\
1 & \text{with probability } \frac{R - E(z)}{z_{\max} - E(z)}
\end{cases}
\]

(2.7)

\[
L(z) = P(z | E(z) \geq R).
\]

(2.10)

We close this section by discussing briefly the case where the option payoff is not convex. In such a case the expressions \(\hat{c}_j\) are no longer a convex function of the conditional mean of the asset return \(\hat{z}_j = E[S_r / S_0 | s_r / s_0 < z_j]\) in (2.3). In fact, the \(\hat{c}_j\)’s may not even form an increasing function of the conditional means. Nonetheless, the program (2.1) yields a maximum and a minimum that are found on the convex hull of the graph of the \(\hat{c}_j\)’s plotted as functions of the conditional means. Although closed form solutions for the bounds don’t exist in this case, their values may be computed numerically for one period, and then extended recursively in the multiperiod case as in the next section. These cases are particularly important when the returns are not iid, as in the case of stochastic volatility examined in section 6.

2. Multiperiod Bounds: the General Case

A. The bounds for iid returns

It is easy to extend the bounds to a multiperiod context under the assumption of iid stock returns. The assumptions necessary for such an extension are the counterpart of
assumptions (a) and (b) of the previous section. There must be at least one investor in the market holding only the underlying asset and the riskless asset. The investor maximizes recursively a concave utility function over a horizon that is equal to or larger than the time $T$ to option expiration. The objective is either terminal wealth or consumption with a final endowment. It is well known that in the absence of transaction costs the indirect utility at any intermediate time point is a concave function of wealth at that point, a property that is sufficient to establish the monotonicity of the state contingent discount factors in every period.

Given this property, we can apply a recursive version of the linear programming problem (2.1), in which at each iteration the convex functions $\overline{C}(Sz_j)$ and $\underline{C}(Sz_j)$ will replace the call payoffs $c_j$ in the maximization and minimization problems respectively. Under iid returns the risk neutral distributions $U(z)$ and $L(z)$ remain the same in every period, given by (2.4) and (2.5) or (2.7) and (2.10) in the discrete and continuous cases, respectively. Given a current stock price $S_t$ at time $t \leq T$, and with the superscripts $U$ and $L$ denoting expectations under the corresponding distributions $U(z)$ and $L(z)$ of the one-period stock return $z = S_{t+1} / S_t$, the option bounds $\overline{C}_t(S_t)$ and $\underline{C}_t(S_t)$ become

$$
\overline{C}_t(S_t) = \frac{1}{R} E^U[C_{t+1}(S_t, z) | S_t]
$$

$$
\underline{C}_t(S_t) = \frac{1}{R} E^L[C_{t+1}(S_t, z) | S_t]
$$

(3.1)

In the special case where $z_t = \min\{z\} = 0$ and (2.8) holds in a single period the upper bound $\overline{C}_t(S_t)$ can be estimated very simply by the law of iterated expectations. It is given by

$$
\overline{C}_t(S_t) = \frac{1}{[E(z)]^{T-t}} E^U[\max(S_T - K, 0) | S_t]
$$

(3.1)'

In a distribution with iid returns the multiperiod bounds can be extended to American options with very little reformulation. The following expressions give the bounds for American call options on stocks with a constant dividend yield $\gamma$, as well as for American put options. They may be proven very simply by induction.

\[\text{References}\]

\[\text{Note}\]

15For a more detailed analysis see Perrakis (1986) and Ritchken and Kuo (1988).

16Note that (3.1)' also holds in the presence of proportional transaction costs in the underlying asset if it is multiplied by the roundtrip transaction costs. See Proposition 1 of Constantinides and Perrakis (2002).
\[
\bar{C}_{A,t}(S_t) = \frac{1}{R} E^U [\max \{ S_t z_{t+1} (1+\gamma) - K, \bar{C}_{A,t+1}(S_{t+1}) \}] | S_t, \]
\[
C_{A,t}(S_t) = \frac{1}{R} E^L [\max \{ S_t z_{t+1} (1+\gamma) - K, C_{A,t+1}(S_{t+1}) \}] | S_t, \] (3.2)
\[
\bar{C}_{A,T}(S_T) = C_{A,T}(S_T) = (S_{T-1} z_T (1+\gamma) - K)^+. \]

\[
\bar{P}_{A,t}(S_t) = \frac{1}{R} E^U [\max \{ K - S_t z_{t+1}, \bar{P}_{A,t+1}(S_{t+1}) \}] | S_t, \]
\[
P_{A,t}(S_t) = \frac{1}{R} E^L [\max \{ K - S_t z_{t+1}, P_{A,t+1}(S_{t+1}) \}] | S_t, \] (3.3)
\[
\bar{P}_{A,T}(S_T) = P_{A,T}(S_T) = (K - S_{T-1} z_T)^+. \]

B. The general case of non-iid returns

In a general model of security returns in which the iid assumption does not hold the option price at time \( t \) under the no arbitrage approach is the conditional expectation of its payoff times the stochastic discount factor given the information available at time \( t \). Let \( (\Omega, \mathcal{F}, P) \) a complete probability space where \( \Omega \) comprises all the possible sequences of states of the economy until the expiration of the option, \( \mathcal{F} \) is the sigma algebra generated by \( \Omega \), and \( P \) is the subjective probability measure representing the beliefs of an investor. The option price at time \( t \) is

\[
c_t = E^P [\max(S_t - K, 0) Y_t | \mathcal{F}_t] \]

Where \( \mathcal{F}_0 \subset \mathcal{F}_1 \subset \cdots \subset \mathcal{F}_t \) is the filtration generated by \( \Omega \), \( \mathcal{F}_t \) represents the information set available to the investor at time \( t \), and \( Y_T \) is the pricing kernel. By the law of iterated expectations

\[
c_t = E^P [E^P [\max(S_t - K, 0) Y_{t+1} | \mathcal{F}_{t+1}] | \mathcal{F}_t] \]
\[
= E^P [c_{t+1} Y_{t+1} | \mathcal{F}_t] \]

When the iid assumption is relaxed the main difficulty in applying the stochastic dominance approach is the possibility of non-convexities of the call option bounds with respect to the price of the underlying asset at any time \( t < T \). In a single period the convexity of the bounds is strictly a function of the convexity of the call payoff with respect to the price of the underlying asset. In a multiperiod or in a continuous time model the convexity of the payoff is not always sufficient to guarantee the convexity of the option price. This issue has been examined in detail by Bergman et al (1996), who provide necessary and sufficient conditions for convexity to hold. They show that convexity holds in all univariate diffusion cases, as well as in several diffusion cases in which volatility is stochastic. For all cases in which convexity holds problem (2.1) can be
rewritten in recursive form as follows

\[
\min(\max) c_t = \sum_{j=1}^{n} c_{t+1,j} p_{i_{t+1,j}} Y_{i_{t+1,j}}
\]

subject to:

\[
S_t = \sum_{j=1}^{n} s_{i_{t+1,j}} p_{i_{t+1,j}} Y_{i_{t+1,j}}
\]

\[
B_t = \sum_{j=1}^{n} p_{i_{t+1,j}} Y_{i_{t+1,j}}
\]

\[
0 \leq p_{i_{t+1,j}} \leq 1
\]

\[
Y_{t+1,1} \geq Y_{t+1,2} \geq \ldots \geq Y_{t+1,n}
\]

where the variables \( s_{i_{t+1}}, c_{i_{t+1}}, p_{i_{t+1}}, Y_{i_{t+1}} \) are conditional on the information available at time \( t \).

Then, by applying successively the results of the two-period problem we can find expressions equivalent to (3.1) for non-iid returns. For instance, the upper bound yields at every time period

\[
c_t \leq \frac{1}{R} E^{U_t} [c_{i_{t+1}} | \mathcal{F}_t] \leq \frac{1}{R} E^{U_t} [\overline{C}_{i_{t+1}} | \mathcal{F}_t]
\]

and by repeatedly applying the law of iterated expectations we get

\[
\overline{C}_t = \frac{1}{R^n} E^{U_t \circ \cdot \cdot \cdot \circ U_t} [\max(S^{(n)}_n - K, 0) | \mathcal{F}_t]
\]

where \( z^{(n)} \) is the \( n \) period return and \( U^{(n)} \) is its distribution. When the returns are iid \( U^{(n)} \) is the the \( n \)-period convolution of the upper bound distribution derived in the previous section. In the more general case the distribution of \( S_{i_{t+1}} \) may depend on \( S_t \) but the option price continues to be convex in \( S_t \). In such cases the option upper bound is still given recursively by\(^{17}\) (3.1), with the distribution \( U \) given by (2.7), except that the return distribution \( P(z) \) now depends on \( S_t \). While a closed form solution for the bound would be difficult to derive, the bounds may be easily computed via Monte Carlo simulations of the distribution \( U(z) \) generated at each time step from the corresponding \( P(z) \). A similar process may also be applied for the derivation of the lower bound. The procedure remains virtually unchanged when \( \hat{z}_n < R \). In such a case the monotone ordering of the state contingent discount factors is reversed in (3.4) and it is (2.2)' and (2.3)', or (2.7)' and (2.10)', that provide the appropriate bounds for that particular subperiod.

In the remaining sections of this paper we examine the multiperiod bounds given by (3.1)\(^{17}\)

\(^{17}\)A similar recursion can be applied when \( z_1 = \min\{z\} = 0 \) and (2.8) applies in every period.
or (3.4) in several cases of practical interest. It is the limiting behavior of these expressions as trading becomes progressively more dense and we pass from discrete to continuous time that is of interest in this paper. It will be shown that this limiting behavior contains as special cases virtually the entire set of option pricing models that have appeared in the literature till now, most of them derived by arbitrage methods.

3. Option Bounds in Continuous Time: the Diffusion Case

The limiting behavior of the bounds in (3.1) was examined in Perrakis (1988) for the special case of a stock return following a trinomial distribution. It was shown that when that distribution tended to a diffusion process the limit of both upper and lower bounds was the Black-Scholes option price. The convergence criteria used in that study were the ones provided by Merton (1982) for iid returns following a general multinomial process. Since the bounds are available in closed form in such a case, it suffices to show that the limiting form of the multiperiod convolutions of the distributions \( U(z) \) and \( L(z) \) given by (2.7) and (2.9) or (2.10) is a risk neutral diffusion with the same constant volatility as the initial process.

This line of approach is, unfortunately, not available when the underlying stock returns are not iid. Although the Merton (1982) criteria for the convergence to a diffusion of the multinomial discretization of the underlying stochastic process are still valid, they are not very useful in characterizing the limiting process. Further, the option bounds themselves are available only as recursive expressions of time-varying distributions, whose limiting form is not easy to ascertain under general conditions. For this reason we shall examine the behavior of the bounds for a more general diffusion process by adopting a different discretization of the stochastic process and a more general approach to convergence analysis.

We consider the most general case of a diffusion process followed by the stock price in continuous time

\[
dS = \mu(S)dt + \sigma(S)dW,
\]

where \( W \) is a Wiener process with \( E(dW) = 0 \) and \( d<W,W> = dt \) and \( \mu(S), \sigma(S) \) are unspecified functions; in the traditional Black-Scholes model both functions are linear with constant coefficients, \( \mu(S) = \mu S \) and \( \sigma(S) = \sigma S \). We seek a discrete time Markovian stochastic process over the interval \([0, T]\) to option expiration that would converge to (4.1) as the length \( \Delta t \) of the elementary time period tends to zero. The weak convergence property for such processes\(^\text{18}\) stipulates that for any sequence of discrete Markov processes \( \{S, l \Delta t\}^m \) with associated probability measure \( P^m \) and any continuous

\(^{18}\)For more on weak convergence for Markov processes see Ethier and Kurz (1986), or Strook and Varadhan (1979).
bounded function $f$ we have $E^P \left[ f \left( S_T^m \right) \right] \to E^P \left[ f \left( S_T \right) \right]$, where the measure $P$ corresponds to the process given by (4.1). $P_m$ is then said to converge weakly to $P$ and $S_T^m$ is said to converge in distribution to $S_T$. In our case, once weak convergence to (4.1) has been established for the chosen discretization we must examine the convergence of the transformations $U$ and $L$ of $P$ corresponding to the upper and lower call option bounds respectively. The call option price bounds would then be the limits of the expectation of the call payoff under the limiting distributions, and a unique option price results if both $U$ and $L$ converge to the same limit.

There are several ways to verify the weak convergence of Markov processes. For instance, a necessary and sufficient condition for the convergence to a diffusion is the Lindeberg condition, which was used by Merton (1982) to develop criteria for the convergence of multinomial processes. Let $X_t$ denote a discrete multidimensional stochastic process. The Lindeberg condition, a necessary and sufficient condition that $X_t$ converges weakly to a diffusion, is that for any fixed $\delta > 0$ we must have

$$\lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{|y-x|>\delta} Q_{\Delta t}(x,dy) = 0$$

(4.2)

where $Q_{\Delta t}(x,dy)$ is the transition probability from $X_t = x$ to $X_{t+\Delta t} = y$ during the time interval $\Delta t$. Intuitively, it requires that $X_t$ does not change very much when the time interval $\Delta t$ goes to zero.

When the Lindeberg condition is satisfied, the following limits exist

$$\lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{|y-x|>\delta} (y_i - x_i) Q_{\Delta t}(x,dy) = \mu_i(x)$$

(4.3)

$$\lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{|y-x|>\delta} (y_i - x_i)(y_j - x_j) Q_{\Delta t}(x,dy) = \sigma_{ij}(x)$$

(4.4)

The conditions (4.2), (4.3) and (4.4) are equivalent to the weak convergence of the discrete process to a diffusion process with the generator

$$\mathcal{A} = \frac{1}{2} \sum_{i=1}^{d} \sigma_{ij} \frac{\partial^2}{\partial x_i \partial x_j} + \sum_{i=1}^{d} \mu_i \frac{\partial}{\partial x_i}$$

(4.5)

where $d$ is the dimension of the process. By the definition of the generator, for each bounded, real valued function $f$ we have
The limit diffusion process can also be described by the d-dimensional stochastic differential equation
\[ dx = \mu(x)dt + \sigma(x)dW \]
which corresponds in our case to the uni-dimensional equation (4.1) when \( x = S \). To make the convergence results meaningful, it is assumed that this differential equation has a solution.\(^{19}\) We shall examine the convergence of the option bounds in continuous time under the following discrete time representation of the stock return process
\[ S_{t+\Delta t} - S_t = \mu(X_t)\Delta t + \sigma(X_t)\varepsilon_{t+\Delta t}\sqrt{\Delta t} \] \hspace{1cm} (4.7)

In (4.7) \( X_t \) is a vector of state variables known at time \( t \) and including, but not necessarily limited to \( S_t \), and \( \varepsilon_{t+\Delta t} \) has a bounded continuous distribution of mean zero and variance one, \( \varepsilon_{t+\Delta t} \sim D(0,1) \) and \( 0 < \varepsilon_{\min} \leq \varepsilon_{t+\Delta t} \leq \varepsilon_{\max} \), but otherwise unrestricted. First we establish that this representation is a valid discretization of the continuous time stochastic process by means of the following result, whose proof is in the appendix.

**Lemma 1.** The discrete process described by equation (4.7) converges weakly to the diffusion (4.1).

Once we have proven the lemma we then apply it to the process governing the stock return\(^{20}\)
\[ (S_{t+\Delta t} - S_t) / S_t \equiv z_{t+\Delta t} = \mu(X_t)\Delta t + \sigma(X_t)\varepsilon_{t+\Delta t}\sqrt{\Delta t}. \] \hspace{1cm} (4.8)

The limit of (4.8) is the following continuous time process
\[ \frac{dS}{S} = \mu(X_t)dt + \sigma(X_t)dW \] \hspace{1cm} (4.9)

where \( \mu(\cdot) \) and \( \sigma(\cdot) \) are functions of \( X_t \) such that equation (4.9) has a solution. Suppose now that we have chosen a certain \( \Delta t \) and are at some time \( t < T \), observing the state variables \( X_t \) in (4.8) and ascertaining that \( \mu > R - 1 \equiv r \). We have already evaluated the option bounds \( \overline{C}(S_{t+\Delta t}) = \overline{C}(S_t(1 + z_{t+\Delta t})) \) and \( \underline{C}(S_{t+\Delta t}) = \underline{C}(S_t(1 + z_{t+\Delta t})) \).

\(^{19}\) For instance, a Lipschitz condition for the functions \( \mu(\cdot) \) and \( \sigma(\cdot) \) provides the existence and uniqueness of a strong solution. This condition is satisfied by all the models used in option pricing.

\(^{20}\) Note that \( z_{t+\Delta t} \) differs from the variable \( z \) used in equation (3.1) since the latter is the wealth relative while the former is the wealth relative minus one and has, therefore, the same distribution.
We then evaluate the upper and lower bounds at \( t \) by applying the relations\(^{21}\)

\[
\bar{C}(S_t) = E^U[C(S_t(1 + z_{t,t+\Delta t})) | \mathcal{F}_t]
\]

\[
\underline{C}(S_t) = E^L[C(S_t(1 + z_{t,t+\Delta t})) | \mathcal{F}_t]
\]

where \( \bar{C}(S_t) = \underline{C}(S_t) = \max\{S_t - K, 0\} \), the superscripts \( U \) and \( L \) denote the transformations of the distribution of the one-period return given in (2.7) and (2.10) respectively, with the return \( z_{t,t+\Delta t} \) given by (4.8). If, on the other hand, the state variables \( X_t \) are such that \( \mu \leq r \) then the expectations are taken with respect to the transformations of the distribution given by (2.7)' and (2.10)'.

With such a procedure we can then generate the upper and lower bounds at time zero corresponding to any path of stock prices drawn from the discrete process (4.8); the distribution of the error term \( \epsilon_{t,t+\Delta t} \) can be a very simple one, such as a uniform distribution centered at 0 with its variance set equal to 1. Of particular interest, however, is the existence of a limit to these bounds as \( \Delta t \to 0 \) and (4.8) tends to (4.9). These limits are expressed by the following two propositions that form the main results of this section and whose proof is in the appendix.

**Proposition 1.** When the underlying asset follows a continuous time process described by (4.9) the stochastic dominance upper bound of a European call or put option converges to the discounted expectation of the terminal payoff of an option on an asset whose dynamics are described by the process

\[
\frac{dS}{S} = rdt + \sigma(X_t)dW
\]

where \( r \) is the (continuous time) riskless rate of interest.

**Proposition 2.** Under the conditions of Proposition 1 the stochastic dominance lower bound of a European call or put option converges to the same limit as the upper bound.

These remarkable results establish the formal equivalence of the stochastic dominance approach to the prevailing arbitrage methodology for plain vanilla option prices whenever the underlying asset dynamics are generated by a diffusion or Ito process, no matter how complex. The equivalence holds for stock options as well as for index options, even though the assumption that there must be an investor holding only the stock and the riskless asset may not always appear reasonable. Note that the univariate Ito process is the only type of asset dynamics, corresponding to dynamically complete markets, for which options can be priced by arbitrage considerations alone. The stochastic volatility, GARCH processes, and mixed jump-diffusion models need

\(^{21}\) The recursive evaluation shown in (4.10) assumes that the recursive evaluation of the bounds shown in (3.4) is still valid, which is the case only if the option price is convex at any time \( t \) with respect to the price of the underlying asset. While this holds always for the univariate diffusions, the cases of multivariate diffusions like stochastic volatility are more complex and will be examined in Section 6. If convexity does not hold (4.10) still holds but the recursive expectations do not necessarily bind the option price.
additional assumptions beyond arbitrage in order to complete the market.

Valuation of the option by Monte Carlo simulation of the bounds for the cases where no closed-form expression for the option price exists is certainly an alternative to an option value computed as a discounted payoff of paths generated by the Monte Carlo simulation of (4.11). While there may not be any computational advantages in going through the bounds route to option valuation, the fact that both upper and lower bound tend to the same limit may provide a benchmark for the accuracy of the valuation, in contrast to the direct simulation of (4.11). Further, the possibility that the bounds may provide an accurate approximation of the option price in cases where the exact form of the asset dynamics is unknown is an empirical question that merits consideration, even though it lies beyond the scope of this paper. In the following sections we examine the behavior of the bounds under asset dynamics that go beyond the general process for dynamically complete markets described by (4.1).

4. Option Bounds in Continuous Time and Incomplete Markets
   I: Mixed Jump-Diffusion Processes

Jump-diffusion processes characterize the dynamics of the underlying asset price distribution whenever there are discontinuous jumps in the time path of the stock price caused by the sudden and unexpected arrival of important information. Such jumps have long been recognized as an important source of market incompleteness. Their presence makes the valuation of options solely by arbitrage methods infeasible, except in a binomial model.\footnote{See Cox and Rubinstein (1985, pp. 365-368).} As for the stochastic dominance approach, it was shown that the two bounds converge to two different option values at the limit of continuous trading even in the case of a very simple three-state jump process (up, down, and stay the same).\footnote{See Proposition 6 in Perrakis (1988).}

When there are jumps in the underlying asset price distribution it is not possible to replicate the option with a portfolio comprising the riskless asset and the underlying asset. The pricing of the option requires extra assumptions regarding the jump risk. The most common assumption, originally introduced by Merton (1976), is that the jump risk is diversifiable. In such a case the market will not pay a risk premium over the riskless rate for bearing the jump risk and risk neutral pricing applies by assuming that the jump probabilities are risk neutral. With such an assumption a closed-form expression for the option price was provided by Merton for the case where the amplitude of the jump size follows a lognormal distribution. Alternative approaches for valuing options in jump-diffusion cases have been provided by Amin and Ng (1993), Amin (1993) and Bates (1991, 1996).\footnote{See also Bakshi, Cao and Chen (1997), who added jump components to a stochastic volatility model. More recently Duffie, Pan and Singleton (2000) have introduced option pricing models for underlying assets that contain jumps in both asset returns and their stochastic volatility.}

In this section we examine the stochastic dominance approach to option pricing in the

\footnote{See Cox and Rubinstein (1985, pp. 365-368).}
\footnote{See Proposition 6 in Perrakis (1988).}
\footnote{See also Bakshi, Cao and Chen (1997), who added jump components to a stochastic volatility model. More recently Duffie, Pan and Singleton (2000) have introduced option pricing models for underlying assets that contain jumps in both asset returns and their stochastic volatility.
case of underlying assets whose returns follow jump-diffusion processes. As with the general diffusion case, we first provide a discretization of the continuous time process that converges at the limit to the given jump-diffusion process. The option bounds are derived by the stochastic dominance approach from such a discretization by applying the risk neutral transformations (2.7) and (2.10) to the discrete one-period distribution. The two transformed distributions are then shown to converge at the continuous time limit to two different option prices. These prices correspond to two different risk neutral jump-diffusion processes, each one of which prices options in a manner similar to the Merton (1976) assumption of diversifiable jump risk. We provide two partial differential equations (pde) satisfied by the upper and lower bounds respectively. Last but not least, we show that the two bounds contain all the jump-diffusion option prices that have appeared in earlier studies, including the Merton (1976) price. We assume that the underlying asset returns follow the process

\[
\frac{dS_t}{S_t} = (\mu_t - \lambda J_t)dt + \sigma_t dW_t + J_t dN_t,
\]

(5.1)

where the last term is a jump component added to the diffusion. Although our results apply to the more general case where both \( \mu_t \) and \( \sigma_t \) are functions of \( S_t \), we shall assume in what follows that \( \mu_t = \mu, \sigma_t = \sigma, \lambda_t = \lambda \) and \( J_t = J \), in line with earlier studies; we shall also assume that \( \mu > r \). The variable \( J \) represents the logarithm of the jump size. It is a random variable with distribution \( D_J \) with mean \( \mu_J \) and variance \( \sigma_J \). \( N \) is a Poisson counting process with intensity \( \lambda \). In most of the literature it is assumed that \( D_J \) is a normal distribution.

The first step in deriving the bounds on this process is to find a discrete approximation that converges weakly to (5.1). It will be shown that the following process is such an approximation, with \( z_{t,t+\Delta t} \) denoting the logarithmic return.

\[
z_{t,t+\Delta t} = (\mu - \lambda \mu_J)\Delta t + \sigma \varepsilon \sqrt{\Delta t} + J \Delta N
\]

(5.2)

where \( \varepsilon \) is a random variable with a given distribution, either a bounded continuous distribution \( D(0,1) \), or even a simple binomial process taking the values \( \pm 1 \) with probability \( 1/2 \). The transition probability of the returns process can be characterized as a mixture of a diffusion and a jump, with corresponding probabilities \( 1 - \lambda \Delta t \) and \( \lambda \Delta t \):

\[
z_{t,t+\Delta t} = \begin{cases} 
  z_d = (\mu - \lambda \mu_J)\Delta t + \sigma \varepsilon \sqrt{\Delta t} & \text{with probability } 1 - \lambda \Delta t \\
  J & \text{with probability } \lambda \Delta t
\end{cases}
\]

\textsuperscript{25} Of these two pde’s only the one corresponding to the upper bound yields a closed-form solution under a lognormal distribution of the amplitude of the jumps. For the lower bound, and for all other jump amplitude distributions, both option bounds can be obtained either through numerical methods or through their characteristic functions following the approach of Heston (1993) and Bates (1996).
It can be easily seen that this process does not satisfy the Lindeberg condition, since

$$\lim_{\Delta t \to 0} \frac{1}{\Delta t} Q_t(\Delta) = \int_{|z_t| > \Delta} dD_J(J) + \lim_{\Delta t \to 0} \frac{1}{\Delta t} \int_{|z_t| > \Delta} (1 - \lambda \Delta t) dD_N(\varepsilon)$$

As shown in the proof of Lemma 1 for the diffusion case, the second integrand is zero for $\Delta t$ sufficiently low. However, the first integrand is strictly positive for any $\Delta t$, implying that the process does not converge to a diffusion in continuous time. The following result, proven in the appendix, shows that (5.2) is a valid discrete time representation of (5.1).

**Lemma 2.** The discrete process described by (5.2) converges weakly to the jump-diffusion process (5.1).

Next we examine the limiting behavior of the stochastic dominance bounds derived from (5.2). We assume, without loss of generality, that the variable $J$ takes both positive and negative values, or that $J_{\min} < 0 < J_{\max}$, implying that the jump amplitude takes values both above and below 1. For the option upper bound we apply (2.7) to the discrete time process defined by (5.1). For such a process we note that as $\Delta t$ decreases, there exists $h$, such that for any $\Delta t \leq h$, the minimum outcome of the jump component is less than the minimum outcome of the diffusion component, $J_{\min} < \mu \Delta t + \sigma \varepsilon_{\min} \sqrt{\Delta t}$. Consequently, for any $\Delta t \leq h$, the minimum outcome of the returns distribution is $J_{\min}$, which is the value that we substitute for $z_{\min}$ in (2.7). With such a substitution we have now the following result, proven in the appendix.

**Proposition 3.** When the underlying asset follows a jump-diffusion process described by (5.1) the upper option bound is the discounted expected payoff of an option on an asset whose dynamics is described by the jump-diffusion process

$$\frac{dS_t}{S_t} = \left[R - (\lambda + \lambda_U) \mu_U^U\right] dt + \sigma dW + J^{U} dN_t$$

where $R$ is the riskless interest rate,

$$\lambda_U = -\frac{\mu - R}{J_{\min}}$$

and $J^{U}$ is a jump with the distribution and mean

$$J^{U} = \begin{cases} J & \text{with probability } \frac{\lambda}{\lambda + \lambda_U} \\ J_{\min} & \text{with probability } \frac{\lambda_U}{\lambda + \lambda_U} \end{cases}$$

$$\mu_U^U = \frac{\lambda}{\lambda + \lambda_U} \mu + \frac{\lambda_U}{\lambda + \lambda_U} J_{\min}$$

The proof of Proposition 3 comes from the convergence of the risk-neutral discrete time.
process defined by (5.2) to the jump-diffusion process given by (5.3). Given now Proposition 3, we can then use the results derived by Merton (1976) for options on assets following jump-diffusion processes with the jump risk fully diversifiable.\textsuperscript{26} Applying Merton’s approach to (5.3) we find that the upper bound on call option prices for the jump-diffusion process (5.1) must satisfy the following pde, with terminal condition \( C(S_T, T) = \max\{S_T - K, 0\} \):

\[
\left[R - (\lambda + \lambda_J)\mu\right] S \frac{\partial \overline{C}}{\partial S} - \frac{\partial \overline{C}}{\partial T} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 \overline{C}}{\partial S^2} + \lambda J E^U [\overline{C}(SJ^U) - \overline{C}(S)] - RC = 0 \quad (5.6)
\]

An important special case is when the lower limit of the jump amplitude is equal to 0, in which case \( J_{\min} = -\infty \) and the process (2.7) is replaced by (2.8). In such a case \( R \) is replaced by \( \mu \) in (5.6), which now becomes

\[
\left[\mu - \lambda J\right] S \frac{\partial \overline{C}}{\partial S} - \frac{\partial \overline{C}}{\partial T} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 \overline{C}}{\partial S^2} + \lambda E[\overline{C}(SJ) - \overline{C}(S)] - \mu \overline{C} = 0 \quad (5.7)
\]

If (5.7) holds and we assume, in addition, that the amplitude of the jumps has a lognormal distribution with \( J \sim N(\mu, \sigma) \), the distribution of the asset price given that \( k \) jumps occurred is conditionally normal, with mean and variance

\[
\mu_k = \mu - k\lambda \mu_J + \frac{k}{T} \ln(1 + \mu_J) \quad (5.8)
\]

\[
\sigma_k^2 = \sigma^2 + \frac{k}{T} \sigma_J^2
\]

Hence, if \( k \) jumps occurred, the option price would be a Black-Scholes expression with \( \mu_k \) replacing the riskless rate \( r \), or \( BS(S, K, T, \mu_k, \sigma_k) \). Integrating (7.7) would then yield the following upper bound, which can be obtained directly from Merton (1976) by replacing \( r \) by \( \mu \).

\[
\overline{C} = \sum_{k=0}^{\infty} \exp[-\lambda(1 + \mu_J)T] \frac{[\lambda(1 + \mu_J)T]^k}{k!} BS(S, K, T, \mu_k, \sigma_k) \quad (5.9)
\]

When the jump distribution is not normal, the conditional asset distribution given \( k \) jumps is the convolution of a normal and \( k \) jump distributions. The upper bound cannot be obtained in closed form, but it is possible to obtain the characteristic function of the bound distribution. Similar approaches can be applied to the integration of equation (5.6), which holds whenever \( 0 > J_{\min} > -\infty \). Closed form solutions can also be found whenever the amplitude of the jumps is fixed as, for instance, when there is only an up and a down jump of a fixed size.\textsuperscript{27} A pde similar to (5.6) also holds if the process has only “up”

\textsuperscript{26} Remark that in the stochastic dominance approach, we do not assume that the jump risk is diversifiable.

\textsuperscript{27} See, for instance, Perrakis (1993).
jumps, in which case $J_{min} = 0$ and the lowest return $z_{min}$ in (2.7) comes from the diffusion component.

Next we examine the option lower bound for the jump-diffusion process given by (5.1) and its discretization (5.2). We apply now (2.10) to the process (5.2) and we prove in the appendix the following result.

**Proposition 4.** When the underlying asset follows a jump-diffusion process described by (5.1), the lower option bound is the discounted expected payoff of an option on an asset whose dynamics is described by the jump-diffusion process

$$\frac{dS_t}{S_t} = \left[ r - \lambda \mu J_t^L \right] dt + \sigma dW_t + J_t^L dN_t$$

where $J_t^L$ is a jump with the truncated distribution $J \mid J \leq J$

The mean of the jump and the value of can be obtained by solving the equations

$$\mu - \lambda \mu_J + \lambda \mu_J^L = r$$
$$\mu_J^L = E(J \mid J \leq J)$$

Observe that (5.11) always has a solution since $\mu > r$ by assumption. From (5.2) it is also clear that as $\Delta t \to 0$ all the outcomes of the diffusion component will be lower than $J$. Therefore, the limiting distribution will include the whole diffusion component and a truncated jump component. The maximum jump outcome in this truncated distribution is obtained from the condition that the distribution is risk neutral, which is expressed in (5.11). As with the upper bound, we can apply the Merton (1976) approach to derive the pde satisfied by the option lower bound, which is given by

$$\left[ r - \lambda \mu J_t^L \right] S \frac{\partial C}{\partial S} - \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 C}{\partial S^2} + \lambda E^{L}(C(SJ^L) - C(S)) - RC = 0$$

with terminal condition $C_T = C(S_T, T) = \max \{S_T - K, 0\}$. The solution of (5.12) can be obtained in closed form only when the jump amplitudes are fixed, since even when the jumps are normally distributed, the lower bound jump distribution is truncated.

We present in Table 5.1 and Figure 5.1 estimates of the bounds under a jump-diffusion process for an at-the-money option with $K = 100$ and maturity $T = 0.25$ years for varying subdivisions of the time to expiration, and with the following annual parameters: $r = 3\%, \mu = 5\%$ to $9\%, \sigma = 10\%, \lambda = 0.3, \mu_J = -0.05, \sigma_J = 7\%$. The jump-diffusion process was approximated by a 300-period tree built according to the method introduced by Amin (1993). The bounds were computed by taking the discounted expectation of the payoff under the time-varying risk neutral probabilities of (3.1) applied to subtrees. The risk neutral price is the Merton (1976) price for this process.

Convergence of the option bounds - Jump Diffusion

$$dS_t = (\mu - \lambda \mu_J) dt + \sigma S_t dW_t + JS_t dN$$

- $S_0 = 100$
- $K = 100$
- $T = 0.25$
- $r = 0.03$
- $\sigma = 0.1$
- $\lambda = 0.3$
- $\mu_J = -0.05$
- $\sigma_J = 0.07$

![Figure 5.1](image-url)
The results shown in Table 5.1 show a spread between bounds of less than 10\%.\textsuperscript{28} It is important to note that this range of allowable prices in the stochastic dominance approach is the exact counterpart of the inability of the “traditional” arbitrage-based approaches to produce a single option price for jump diffusion processes, even when the latter have been augmented in this case by general equilibrium considerations. Indeed, the exact option prices under jump diffusion derived in the well-known studies of Bates (1991), Amin and Ng (1993) and Amin (1993) are all functions of the risk aversion parameter of the CPRA utility function of consumption used in the derivations; see, for instance, equation (27) of Amin and Ng (1993), or equation (33) of Amin (1993). Further, the assumed monotonicity of the state-contingent discount factors of the stochastic dominance approach in an elementary discrete time period also holds in the combination of jump diffusion asset dynamics and CPRA utility of consumption used in the more traditional approaches. The stochastic dominance option bounds are, therefore, a more general approach to option pricing than general equilibrium based on specific forms of the utility function.

5. Option Bounds in Continuous Time and Incomplete Markets II: Stochastic Volatility Processes

In this section we examine the case when the underlying asset follows a multivariate diffusion, as in the stochastic volatility models of Garman (1976), Hull and White (1987), Heston (1993), and many others. We consider again asset dynamics given by equations (4.8)-(4.9), in which the state vector \( \mathbf{X} \) is defined as the pair \( \{S, \mathbf{x}\} \), where \( S \) is the underlying asset price and \( \mathbf{x} \) incorporates other state variables that measure the asset volatility. While equation (4.8) is sufficiently general to extend the validity of the bounds (4.10), with minor reformulation, to option pricing under several cases of stock dynamics following stochastic volatility models, the additional source of randomness over and above the randomness in stock return creates two important difficulties, which may limit the applicability of the stochastic dominance approach. Both can be illustrated by referring to the basic recursive equation (3.4) of the discrete time model.

The first problem that may arise is that the new source of randomness would affect the state contingent discount factors \( \{Y_t\} \) so that their monotone ordering with respect to the values \( S_t \) of the underlying asset would not be preserved. Since the source of randomness that we consider is a parameter of the distribution of \( S_t \), this would imply that the investor utility is affected by this new source of randomness independently from the effect that it may have on \( S_t \). Although this is difficult to rationalize for an investor who invests only in the stock, the option and the riskless asset, such independent “pricing of volatility risk” has been incorporated into the models of Heston (1993) and Bates (1996).\textsuperscript{29}

\textsuperscript{28} The spread is much lower for in-the-money options and reaches about 15\% for the out-of-the money options.

\textsuperscript{29} See the comments by Lamoureux and Lastrapes (1993), p. 9.
The second problem arises from the fact that the convexity of the option bounds with respect to $S_t$ may not be preserved in the recursive application of problem (3.4) to the bounds $C_t(S_t)$ and $C_t(S_t)$. Sufficient conditions for such convexity have been derived in Bergman et al (1996). Most of the stochastic volatility models that have appeared in the literature such as Hull and White (1987), Heston (1993) and Bates (1996) do satisfy them, as do most GARCH models, but Johnson and Shanno (1987) does not.

To illustrate these two problems in the context of our formulation, we rewrite equation (4.8) as follows

\[(S_{t+\Delta t} - S_t) / S_t \equiv z_{t,t+\Delta t} = \mu(S_t)\Delta t + \sqrt{x_t} \varepsilon_{t+\Delta t} \sqrt{\Delta t},\]

where $\eta_t$ is an error term of mean 0 and variance 1, and with correlation $\rho$ between $\varepsilon_t$ and $\eta_t$. Since this is a special case of (4.8), Lemma 1 holds and the limiting form of the model becomes

\[dS = \mu(S_t)dt + \sqrt{x}dW_t, \]

\[dx = m(x_t)dt + s(x_t)\eta_{t+\Delta t} \sqrt{\Delta t}, \quad dW_t = \rho(x_t)dt \]  

Further, the sufficient conditions in Theorem 2 of Bergman et al (1996) state that convexity is preserved if $m(.)$, $s(.)$, $\rho$ and the function $\sigma(X_t)$ are independent of $S_t$. Under such conditions let $Z(x_t)$ denote the stock returns at $t+\Delta t$, with $C(S_tZ(x_t),x_{t+\Delta t})$ being the corresponding option price. This price is convex in $S_tZ$ for any $x_{t+\Delta t}$. We then have

\[C(S_t,x_t) = e^{-r\Delta t}E[m_{t+\Delta t}E[Y_{t+\Delta t}C(S_tZ(x_t),x_{t+\Delta t})|x_{t+\Delta t}][x_t]] \]  

where the state-contingent discount factors for the returns $\{Y_{t+\Delta t}\}$ are monotonically ordered. There is, however, no rule for the ordering of the state-contingent discount factors for volatility $\{m_{t+\Delta t}\}$, unless the volatility is not priced independently, in which case these factors are all equal to 1, in which case we have

\[C(S_t,x_t) = e^{-r\Delta t}E[Y_{t+\Delta t}C(S_tZ(x_t),x_{t+\Delta t})|x_{t+\Delta t}][x_t]. \]  

Under such an assumption we have the following result, proven in the appendix

**Proposition 5:** When the dynamics of the underlying asset follow the stochastic volatility model given by (6.2) and the volatility risk is not priced independently, as in (6.4), the option price $C(S_t,x_t)$ corresponding to its discretization (6.1) is at any time $t \in [0,T-1]$ bound by the following convex recursive expressions
\[
\tilde{C}(S_{T-1}, x_{T-1}) = e^{-r \Delta t} E^{U_{T-1}}[(SZ(x_{T-1}) - K)^+], \quad \tilde{C}(S_{T-1}, x_{T-1}) = e^{-r \Delta t} E^{L_{T-1}}[(SZ(x_{T-1}) - K)^+],
\]

\[
\tilde{C}(S_{t}, x_{t}) = e^{-r \Delta t} E^{U_{t}}[C(S_{t},Z(x_{t}), x_{t+\Delta t})|x_{t+\Delta t}][x_{t}],
\]

\[
\tilde{C}(S_{t}, x_{t}) = e^{-r \Delta t} E^{L_{t}}[C(S_{t},Z(x_{t}), x_{t+\Delta t})|x_{t+\Delta t}][x_{t}], \quad \text{for } t \leq T-1,
\]

where the superscripts denote expectations taken with respect to the risk neutral distributions \(U\) and \(L\) of section 2, which are now conditional on the volatility \(x_{t}\).

Further, Propositions 1 and 2 apply to these bounds as well, which tend to a common value.

Although no closed form solution exists for the option price in such a model, the bounds can be estimated by Monte Carlo methods in their discrete version (6.5), as in the previous section. The case shown in (6.1)-(6.2) includes the Hull and While (1987) and the Heston (1993) models as special cases. In Johnson and Shanno (1987), however, the coefficient of \(W_{t}\) includes also a term in \(S_{t}\) which violates the convexity conditions.

In principle one can also develop option bounds under the more general version of (6.3), in which the state-contingent discount factors for volatility \(\{m_{t+\Delta t}\}\) would have different values than 1. There are no rules for ordering these discount factors, and no restrictions on the shape option function with respect to the volatility. Hence, the resulting bounds would not have a closed form expression and would have to be estimated numerically for any given set of discount factors.

A more promising avenue of approach, which is also consistent with the fundamental assumption (a) of section 2, is to replace (6.3) with the following expression

\[
C(S_{t}, x_{t}) = e^{-r \Delta t} E^{Y_{t+\Delta t}}C(S_{t},Z(x_{t}), x_{t+\Delta t})|x_{t}],
\]

where the state contingent discount factors \(\{Y_{t+\Delta t}\}\) are monotonically ordered with respect to the returns \(Z(x_{t})\) for all future volatilities \(x_{t+\Delta t}\). This is clearly a generalization of the case in (6.4), since the conditional state contingent discount factors given \(x_{t+\Delta t}\) are also monotonically ordered with respect to the corresponding conditional returns in (6.6). On the other hand, the monotone ordering in (6.6) clearly assigns ceteris paribus higher factors to the volatilities that produce lower returns, unlike (6.4). The estimation of the stochastic dominance bounds for an option value given by (6.4) does not have a closed form solution: convexity, which holds for a given volatility \(x_{t+\Delta t}\), does not in general hold across different such volatilities. As noted at the end of section 2, the maximum and minimum in the recursive equation (3.4) must be evaluated numerically. In such a case the bounds also remain distinct even at the limit of continuous trading.

In our numerical work we evaluate the bounds for the following special case of (6.2), the mean-reverting stochastic volatility process, originally presented by Heston (1993)
\[
\frac{dS}{S} = \mu dt + \sqrt{x} dW_t, \\
dx = \kappa (\theta - x) dt + s \sqrt{x} dW_t, \quad dW_t dW_s = \rho(x) dt
\]  
(6.7)

Table 6.1 and Figure 6.1 show the bounds evaluated recursively on the basis of (6.6), as well as the unique value of the limiting form of the bounds when the volatility is not priced,\(^{30}\) for various numbers of subdivisions of the time to expiration. We choose again \(K = 100\) and \(T = 0.25\), with an annual mean return \(\mu\) equal to 0.05 and initial volatility \(\sqrt{x_0}\) equal to 0.1. The mean reversion coefficient for the variance equation \(\kappa = 2\), while the long run return variance is \(\theta = 0.01\) and the volatility of the variance \(s = 0.1\). The riskless rate of interest is 3\% and the correlation of the two Brownian motions is \(\rho = -0.5\). The diagram shows a spread of less than 5\%, which persists as the number of time subdivisions increases. This spread is reflects the uncertainty associated with the price of the volatility risk within the context of our assumption of the existence of an investor holding only the underlying and the riskless asset.

\(^{30}\) Instead of taking the limit of the recursive bounds in (6.5) we evaluated this limit by the Heston approach for a market price of risk equal to zero.
6. Option Bounds in Continuous Time and Incomplete Markets II: GARCH models

Next we examine the GARCH model, which has appeared in a number of different formulations in the literature. It is a discrete time diffusion model in which the volatility in each successive period depends on the error term of the previous period. Financial trading may or may not take place within each period. If no trading occurs within each period then the market is incomplete and no unique price emerges. One possible approach to “complete” the market is the one originally introduced by Duan (1995), who assumes the existence of a representative investor with a constant proportional risk aversion (CPRA) utility function. This assumption allows the derivation of a local risk neutral valuation operator that transforms the actual return probability distribution into a risk neutral one. We illustrate the derivation of the stochastic dominance bounds for the NGARCH specification used by Duan (1995). In that model the asset dynamics are given by
\[
\ln \frac{S_{t+1}}{S_t} = r + \lambda \sqrt{h_{t+1}} - \frac{1}{2} h_{t+1} + \sqrt{h_{t+1}} \epsilon_{t+1}
\]
\[
h_{t+1} = \beta_0 + \beta \beta h_t + \beta \epsilon_t (1 - \theta)^2
\]
\[
\epsilon_{t+1} | \mathcal{F}_t \sim N(0,1)
\]

(7.1)
in which \( h_{t+1} \) denotes the volatility at \( t+1 \), a function of the observed error \( \epsilon_t \) at \( t \), and the parameter \( \lambda \) is proportional to the risk premium of the stock. (7.1) implies in turn the following expression
\[
S_{t+1} = S_t e^V, \quad V \equiv f_1(\epsilon_t, \epsilon_{t-1}) + f_2(\epsilon_t, \epsilon_{t-1}) \epsilon_{t+1}.
\]
(7.2)
The value \( C(S_t, \epsilon_t) \) of an option when the underlying asset follows the dynamics given by (7.1) is given by a discounted recursive expectation with a pricing kernel \( \{Y_{t+1}\} \)
\[
C(S_{T-1}, \epsilon_{T-1}) = R^{-1} E[Y_{T-1} (S_T - K)^+ | \epsilon_{T-1}] \\
C(S_t, \epsilon_t) = R^{-1} E[Y_{t+1} C(S_{t+1}, \epsilon_{t+1}) | \epsilon_t]
\]
(7.3)
A pricing kernel ordered monotonically on the stock price \( S_{t+1} \) does not necessarily define a convex function \( C(S_t, \epsilon_t) \), since the error term \( \epsilon_{t+1} \) enters independently in the function within the expectation. Nonetheless, the set of convex functions defined by a monotone pricing kernel as in (7.3) is clearly nonempty. To see this assume that (7.2) defines a locally risk neutral transformation of the distribution of the error term \( \epsilon_{t+1} \), as in Duan (1995).\textsuperscript{31} Then we have
\[
C(S_{t-1}, \epsilon_{t-1}) = R^{-1} E[Y_{t-1} (S_T - K)^+ | \epsilon_{t-1}] = R^{-1} E^Q[(S_T - K)^+ | \epsilon_{t-1}] \\
C(S_t, \epsilon_t) = R^{-1} E[Y_{t+1} C(S_{t+1}, \epsilon_{t+1}) | \epsilon_t] = R^{-1} E^Q[C(S_t e^V, \epsilon_{t+1}) | \epsilon_t]
\]
(7.4)
It is very easy to see by induction that (7.4) implies the convexity of \( C(S_t, \epsilon_t) \) with respect to \( S_t \). We may now prove the following result, whose proof is identical to that of Proposition 5 and will be omitted.

**Proposition 6:** When the dynamics of the underlying asset follow the GARCH model given by (7.1) then any convex option price \( C(S_t, \epsilon_t) \) corresponding to the valuation model (7.2) is at any time \( t \in [0, T-1] \) bound by the following convex recursive expressions
\[
\tilde{C}(S_{t-1}, \epsilon_{t-1}) = R^{-1} E^{U_{t-1}}[(S_T - K)^+ | \epsilon_{t-1}], \quad \underline{C}(S_{t-1}, \epsilon_{t-1}) = R^{-1} E^{I_{t-1}}[(S_T - K)^+ | \epsilon_{t-1}],
\]

\textsuperscript{31} In spite of this the assumption is not innocuous, since in the presence of transaction costs a unique option price is not defined on the basis of a \( Q \)-distribution.
\[
\tilde{C}(S_t, \varepsilon_t) = R^{-1} \mathbb{E}^{U_t}[\tilde{C}(S_{t+1}, \varepsilon_{t+1})|\varepsilon_t], \\
\underline{C}(S_t, \varepsilon_t) = R^{-1} \mathbb{E}^{L_t}[\underline{C}(S_{t+1}, \varepsilon_{t+1})|\varepsilon_t]
\]
for \( t \leq T-1 \), \hspace{1cm} (7.5)

where the superscripts denote expectations taken with respect to the risk neutral distributions \( U \) and \( L \) of section 2, which are now conditional on the error term \( \varepsilon_t \).

In the numerical results presented below the error term \( \varepsilon_t \) is approximated by a multinomial variable of mean 0 and variance 1, as in the Markov chain approach of Duan and Simonato (2001). The superscript \( \text{RN} \) denotes the risk neutral Duan (1995) and Duan and Simonato (2001) estimates of the option value. We expect the following relationship between the stochastic dominance bounds and the risk neutral option price:

\[ \underline{C}_t \leq C_t^{\text{RN}} \leq \overline{C}_t. \]

Table 7.1 below shows European call and put option bounds, as well as the option price corresponding to the Duan (1995) model, for various values of the time to expiration and the moneyness of the option. The partition of the time interval to option expiration is equal to one day for all times to expiration. The parameters are \( S = 50, r = 0.05 \), and for \( T = 3 \) months (90 partitions corresponding to one day each) the parameters of the NGARCH process are \( \beta_0 = 0.00001, \beta_1 = 0.8, \beta_2 = 0.1, \theta = 0.3 \) and \( \lambda = 0.01 \).

</table>

The table shows that the bounds perform very well. In all but one case the risk neutral price lies within the bounds and the only exception, the one-month in-the-money put, is equal to the upper bound within the limits of the accuracy of our computations.

An alternative assumption that may be used in deriving risk neutral option prices under a
GARCH returns structure is to assume that there is continuous trading within each successive GARCH period. This is the approach taken by Kallsen and Taqqu (1998). Each GARCH subperiod is partitioned in intervals of length \( \Delta t \), and the returns for each such interval are then given by (4.8) with the corresponding constant volatility, and the corresponding stochastic dominance bounds are given by (4.10; the volatility varies as we shift from one GARCH period to the subsequent one. As the partition \( \Delta t \) within each GARCH period becomes progressively finer, with the number of GARCH periods remaining the same, the two bounds also tend to the same value.\(^{32}\) To see this we note that the GARCH model of (7.1) becomes now

\[
\frac{dS_t}{S_t} = (r + \lambda \sqrt{h_t})dt + \sqrt{h_t}dW, \tag{7.6}
\]

where

\[
h_t = \begin{cases} 
    h_0 & \text{if } 0 \leq t < 1 \\
    \beta_0 + \beta_1 h_{[t]} + \beta_2 \left( \ln \frac{S_{[t]}}{S_{[t-1]}} - r + \frac{1}{2} h_{[t]} - \lambda \sqrt{h_{[t-1]}} - c \sqrt{h_{[t-1]}} \right)^2 & \text{if } t \geq 1
\end{cases} \tag{7.7}
\]

In the above formula, \([t]\) is the largest integer number that is less than \( t \). Suppose there are \( n \) GARCH periods till expiration of the option. Then we can use induction to prove that the two stochastic dominance bounds coincide. At any time \( t = n-1 \) the two option bounds obviously coincide, since we have a simple diffusion. Now we can apply induction, by assuming that the bounds coincide for any time \( t = \tau \), where \( \tau < t - 1 \), and then use Lemma 1 and Propositions 1 and 2 to demonstrate that the bounds would also coincide for any time \( t \in [\tau - 1, \tau) \). The common limit of the two bounds is the local risk neutral price of Duan (1995).

7. Conclusions

In this paper we have presented a new approach to option pricing, which we have termed the stochastic dominance approach. This approach derives two bounds on allowable option prices dependent on the entire distribution of underlying asset returns. The distribution can be of any type, but the contingent claims are restricted to options with convex payoffs. We show that the two bounds are discounted payoff expectations under two risk neutral transformations of the original asset dynamics.

We then examined the convergence of the discrete time option bounds derived by stochastic dominance methods in a multiperiod context as trading becomes progressively more dense, under a variety of assumptions about the limiting distribution of the underlying asset returns. We found that this stochastic dominance approach nests

\(^{32}\)Alternatively, the length of the GARCH period itself could tend to zero at the limit. In such a case, the NGARCH process tends to a stochastic volatility model, for which the two bounds coincide. See Duan (1997).
virtually the entire set of option prices available in the literature under a variety of alternative methods, including arbitrage and general equilibrium. Specifically, they nest all the models where the distribution of underlying asset depends on a single random factor, as well as the models in which this same distribution depends on multiple factors, provided the pricing operator depends only on a single factor. They fail only whenever these multiple factors affect also the pricing operator over and above the effect that they may have on the price of the underlying asset.

The stochastic dominance approach depends crucially on the convexity of the option payoffs, which makes it suitable for “plain vanilla” call and put options, but its extension to contingent claims with more complex payoff patterns is uncertain. It is, in principle, possible to apply the single period linear programming approach of section 2 to non-convex payoffs, but the resulting contingent claim bounds would no longer have a closed form solution under general conditions. They would, therefore, not be easily amenable either to multiperiod formulations or to the limiting techniques applied in this paper. Similar difficulties are expected to arise if the pricing operator contains random factors that cannot be represented by the price of the underlying asset.

On the other hand, there are two major advantages of the stochastic dominance approach over alternative derivatives pricing methods. The first one is that it does produce useful results in the presence of market frictions such as transaction costs, in sharp contrast to the arbitrage approach. The second one is that it is not necessary to know the stochastic process governing the evolution of the price of the underlying asset in order to price the derivative, as long as an empirical distribution represented by a histogram of possible future values (or returns) of the asset is available. Such an empirical distribution is sufficient to derive the risk neutral $U$- and $L$-distributions that define the option bounds. The common derivation of these pricing distributions would presumably minimize any possible errors in option price stemming from the choice of the wrong model. The empirical implications of this second advantage should form the object of future research.

---

Appendix

A. Proof of Lemma 1

The proof is similar to the one used by Merton (1982), the only difference being that $\varepsilon_{t+\Delta t}$ is now a bounded continuous random variable rather than a multinomial discrete one. Denote $Q_t(\delta)$ the conditional probability that $|X_{t+\Delta t} - X_t| > \delta$, given the information available at time $t$. Since $\varepsilon_{t+\Delta t}$ is bounded, define $\bar{\varepsilon} = \max |\varepsilon_{t+\Delta t}| = \max(|\varepsilon_{\min}|, |\varepsilon_{\max}|)$. For any $\delta t > 0$, define $h(\delta)$ as the solution of the equation

$$\delta = \mu h + \sigma \bar{\varepsilon} \sqrt{h}.$$ 

This equation admits a positive solution

$$\sqrt{h} = \frac{-\sigma \bar{\varepsilon} + \sqrt{\sigma^2 \bar{\varepsilon}^2 + 4 \mu \delta}}{\mu}.$$ 

For any $\Delta t < h(\delta)$ and for any possible $X_{t+\Delta t}$,

$$|X_{t+\Delta t} - X_t| = \mu \Delta t + \sigma \varepsilon_{t+\Delta t} \sqrt{\Delta t} < \mu h + \sigma \bar{\varepsilon} \sqrt{h} = \delta.$$ 

so $Q_t(\delta) = \text{Pr}(|X_{t+\Delta t} - X_t| > \delta) \equiv 0$ whenever $\Delta t < h$ and hence

$$\lim_{\Delta t \to 0} \frac{1}{\Delta t} Q_t(\delta) = 0.$$ 

The Lindeberg condition is thus satisfied. Equations (4.3) and (4.4) are satisfied by the construction of this discrete process, so the diffusion limit of (4.7) is (4.1), QED.

B. Proof of Proposition 1

We shall consider only the case $\mu > r$; the proof for the case $\mu \leq r$ is similar and is omitted. Under the upper bound probability given by (2.7), the returns process becomes

$$z_{t,t+\Delta t} = \begin{cases} z_{t,t+\Delta t} & \text{with probability } 1 - Q \\ \min z_{t,t+\Delta t} & \text{with probability } Q \end{cases},$$

where $Q$ is the following probability
\[
Q = \frac{E(z) - r \Delta t}{E(z) - \min(z_{t, t+\Delta t})}
\]
\[
= \frac{\mu \Delta t - r \Delta t}{\mu \Delta t - (\mu \Delta t + \sigma \varepsilon_{\min} \sqrt{\Delta t})} = -\frac{\mu - r}{\sigma \varepsilon_{\min}} \sqrt{\Delta t}
\]

From the definition of \( z_{t, t+\Delta t} \) given in (4.8) we get

\[
z_{t, t+\Delta t} = \mu(X_i) \Delta t + \sigma(X_i) \sqrt{\Delta t} \begin{cases} 
\varepsilon_{t, t+\Delta t} & \text{with probability } 1 - Q \\
\varepsilon_{\min} & \text{with probability } Q 
\end{cases}
\]

The random component of the returns in (A1) has a bounded continuous distribution, so the upper bound process satisfies the Lindeberg condition. The upper bound distribution (A1) has the mean

\[
E_{t, t+\Delta t}^U[z_{t, t+\Delta t}] = \mu \Delta t + (1 + \frac{\mu - r}{\sigma \varepsilon_{\min}} \sqrt{\Delta t} (\sigma \sqrt{\Delta t}) E_{t, t+\Delta t}^U \varepsilon_{t, t+\Delta t]}
\]

\[
= \mu \Delta t - \frac{\mu - r}{\sigma \varepsilon_{\min}} \sqrt{\Delta t} (\sigma \sqrt{\Delta t}) \varepsilon_{\min} = r \Delta t
\]

Its variance is

\[
Var_{t, t+\Delta t}^U[z_{t, t+\Delta t}] = \sigma_t^2(X_i) \Delta t \left[ 1 + \frac{\mu - r}{\sigma \varepsilon_{\min}} \sqrt{\Delta t} \right] Var_{t, t+\Delta t}^U \varepsilon_{t, t+\Delta t]}
\]

\[
= \sigma_t^2(X_i) \Delta t \left[ 1 + \frac{\mu - r}{\sigma \varepsilon_{\min}} \sqrt{\Delta t} - \frac{\mu - r}{\sigma \varepsilon_{\min}} \sqrt{\Delta t} \varepsilon_{\min}^2 \right]
\]

\[
= \sigma_t^2(X_i) \Delta t
\]

Consequently, the upper bound process converges weakly to the diffusion (4.11).

**C. Proof of Proposition 2**

As with the proof of Proposition 1, we shall consider only the case \( \mu > r \). Under the probability distribution given by (2.10) for the lower bound the transformed returns process becomes

\[
z_{t, t+\Delta t} = \mu(X_i) \Delta t + \sigma(X_i) \hat{\varepsilon} \sqrt{\Delta t},
\]
where \( \hat{\epsilon}_t \) is a truncated random variable \( \{ \hat{\epsilon}_t \mid \epsilon_t < \bar{\epsilon} \} \), with \( \bar{\epsilon} \) found from the condition 
\[ E^L[z_{t,t+\Delta t}] = r\Delta t. \]
Since \( \hat{\epsilon}_t \) is truncated from a bounded continuous distribution the Lindeberg condition is satisfied. The risk neutrality of the lower bound distribution implies that

\[ \mu \Delta t + \sigma \sqrt{\Delta t} E[\hat{\epsilon}_t] = r\Delta t, \]

and the mean of \( \hat{\epsilon}_t \) is

\[ E[\hat{\epsilon}_t] = -\frac{\mu - r}{\sigma} \sqrt{\Delta t} \quad (G.2) \]

Since this random variable is drawn from a distribution that is truncated from the distribution \( D_D \) of \( \epsilon_t \) we get

\[ E[\hat{\epsilon}_t] = \frac{1}{\Pr(\epsilon_t < \bar{\epsilon}_t)} \int_{\epsilon_{\text{min}}}^{\bar{\epsilon}_t} \epsilon_t dD_D(\epsilon_t). \quad (G.3) \]

We picked \( \epsilon_t \) such that \( E_t[\epsilon_t] = 0 \) and we have

\[ \int_{\epsilon_{\text{min}}}^{\epsilon_{\text{max}}} \epsilon_t dD_D(\epsilon_t) = \int_{\epsilon_{\text{min}}}^{\bar{\epsilon}_t} \epsilon_t dD_D(\epsilon_t) + \int_{\bar{\epsilon}_t}^{\epsilon_{\text{max}}} \epsilon_t dD_D(\epsilon_t) = 0. \quad (G.4) \]

Then, from (A2)-(A4) we get

\[ \frac{\mu - r}{\sigma} \sqrt{\Delta t} = \frac{1}{\Pr(\epsilon_t < \bar{\epsilon}_t)} \int_{\epsilon_{\text{min}}}^{\bar{\epsilon}_t} \epsilon_t dD_D(\epsilon_t) \geq \frac{1}{1 - \Pr(\epsilon_t > \bar{\epsilon}_t)} \int_{\epsilon_{\text{min}}}^{\epsilon_{\text{max}}} \epsilon_t dD_D(\epsilon_t) = \frac{\bar{\epsilon}_t \Pr(\epsilon_t > \bar{\epsilon}_t)}{1 - \Pr(\epsilon_t > \bar{\epsilon}_t)}. \quad (G.5) \]

From the last inequality of (A5) we get

\[ \Pr(\epsilon_t > \bar{\epsilon}_t) \leq \frac{\mu - r}{\sigma} \sqrt{\Delta t} \frac{\sqrt{\Delta t}}{\bar{\epsilon}_t + \frac{\mu - r}{\sigma} \sqrt{\Delta t}} = O(\sqrt{\Delta t}). \quad (G.6) \]

(A6) implies that as \( \Delta t \to 0 \) the probability for all \( \epsilon_t > \bar{\epsilon} \) tends to zero. Therefore, the limit lower bound distribution contains all the possible outcomes of \( \epsilon_t \). This result is used to compute the variance of \( \hat{\epsilon}_t \).
\[
\text{Var}(\hat{e}_i) = E[\hat{e}_i^2] - (E[\hat{e}_i])^2
\]
\[
= \frac{1}{\Pr(e_i < \bar{e}_i)} \int_{e_{\min}}^{e_{\max}} e_i^2 dD_e(e_i) - \left(\frac{\mu - r}{\sigma}\right)^2 \Delta t
\]
\[
= \int_{e_{\min}}^{e_{\max}} e_i^2 dD_e(e_i) - \left(\frac{\mu - r}{\sigma}\right)^2 \Delta t
\]
\[
= 1 - \left(\frac{\mu - r}{\sigma}\right)^2 \Delta t \sim 1,
\]

where the third equality applies the conclusion derived from (A6) and the last equality uses the fact that

\[
\text{Var}(e_i) = \int_{e_{\min}}^{e_{\max}} e_i^2 dD_e(e_i) = 1
\]

It follows that

\[
\text{Var}_i^t[z_{i,t+\Delta t}] = \sigma^2 \Delta t + O(\Delta t)^2
\]

The diffusion limit is, therefore, the process described by equation (4.11), QED.

**D. Proof of Lemma 2**

As shown in the proof of Lemma 1, the first two terms of (5.2) converge to a diffusion. The generator of this diffusion is

\[
\mathcal{A}f = \lim_{\Delta t \to 0} \frac{E[f(z_{i,t+\Delta t}, t+\Delta t)] - f(z_{i,t}, t)}{\Delta t}
\]
\[
= (\mu - \lambda \mu_s) S \frac{\partial f}{\partial S} + \frac{\partial f}{\partial t} + \frac{1}{2} \sigma_i^2 S^2 \frac{\partial^2 f}{\partial S^2}.
\]

Denote \( \mathcal{A}^\Delta_t \) the generator of the discrete process described by (5.2). This generator converges to

\[
\lim_{\Delta t \to 0} \mathcal{A}^\Delta_t f = \lim_{\Delta t \to 0} \frac{E[f(z_{i,t+\Delta t}, t+\Delta t)] - f(z_{i,t}, t)}{\Delta t}
\]
\[
= \lim_{\Delta t \to 0} \frac{E[f(z_{D,i,t+\Delta t}, t+\Delta t)] - f(z_{D,i,t}, t)}{\Delta t}
\]
\[
+ \frac{\lambda \Delta t}{\Delta t} E[f(z_{j,i,t+\Delta t}, t+\Delta t)] - f(z_{j,i}, t)
\]
\[
= (\mu - \lambda \mu_s) S \frac{\partial f}{\partial S} + \frac{\partial f}{\partial t} + \frac{1}{2} \sigma_i^2 S^2 \frac{\partial^2 f}{\partial S^2} + \lambda E[f(S)] - f(S),
\]

(G.7)
which is the generator of (5.1), QED.\(^{34}\)

E. Proof of Proposition 3

As with Propositions 1 and 2, we consider the multiperiod discrete time bounds of section 2, obtained by successive expectations under the risk-neutral upper bound distribution. We then seek the limit of this distribution as \(\Delta t \to 0\). The probability \(Q\) used in equation (2.7) is given by

\[
Q = \frac{E(z) - r\Delta t}{E(z) - \min J} = \frac{(\mu - r)\Delta t}{\mu\Delta t - \min J} = \lambda_U \Delta t,
\]

where

\[
\lambda_U = -\frac{\mu - r}{\min J},
\]

since the expected return under the subjective probability distribution is

\[
E(z_{t+\Delta t}) = (1 - \lambda\Delta t)(\mu - \lambda J)\Delta t + \lambda J\Delta t = \mu\Delta t + o(\Delta t).
\]

Observe that \(\lambda_U\) is always positive since \(\min J < 0\) and \(E(z) > r\Delta t\). Hence, the discrete time upper bound process is

\[
z_{t,t+\Delta t} = \begin{cases} 
  z_D & \text{with probability } (1 - \lambda\Delta t)(1 - \lambda_U\Delta t), \\
  J & \text{with probability } \lambda\Delta t(1 - \lambda_U\Delta t), \\
  \min J & \text{with probability } \lambda_U\Delta t.
\end{cases}
\]

By removing the terms in \(o(\Delta t)\), the upper bound process becomes

\[
z_{t,t+\Delta t} = \begin{cases} 
  z_D & \text{with probability } 1 - (\lambda + \lambda_U)\Delta t \\
  J^U & \text{with probability } (\lambda + \lambda_U)\Delta t
\end{cases},
\]

(G.8)

where \(J^U\) is given by (5.5). This is a mixture of the diffusion component and a jump with intensity \(\lambda + \lambda_U\). It can be readily verified that the upper bound process is risk neutral by construction. By Lemma 2, therefore, it converges weakly to a jump-diffusion process.

\(^{34}\)See for instance Merton (1992) for a discussion on the generators of diffusions and jump processes.
with the generator

\[ A^U f = \left[ r - (\lambda + \lambda_t) \mu_t^U \right] S \frac{\partial f}{\partial S} + \frac{\partial f}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 f}{\partial S^2} + \lambda_t E^U \left[ f(S^J) - f(S) \right]. \]  

(G.9)

This process, however, corresponds to (5.3), QED.

**F. Proof of Proposition 4**

The proof is very similar to those of Lemma 2 and Proposition 3. We apply equation (2.10) and observe that, as with the upper bound, the lower bound distribution over \((t, t + \Delta t)\) is a mixture of the diffusion component and a jump of intensity \(\lambda\) and log-amplitude distribution \(J^L\), the truncated distribution \(\{ J \mid J \leq \bar{J} \} \).

\[ z_{t, t + \Delta t} = \begin{cases} 
z_{t, t + \Delta t} & \text{with probability } 1 - \lambda \Delta t \\
J^L & \text{with probability } \lambda \Delta t
\end{cases} \]  

(G.10)

By Lemma 2 this process converges weakly for \(\Delta t \to 0\) to a jump-diffusion process with generator

\[ A^L f = \left[ r - \mu_t^L \right] S \frac{\partial f}{\partial S} + \frac{\partial f}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 f}{\partial S^2} + \lambda E^L \left[ f(S^J) - f(S) \right]. \]  

(G.11)

(A.11), however, corresponds to (5.10), QED.

**G. Proof of Proposition 5**

Let \(\Delta t = \frac{T}{n}\) denote the length of the discrete time period. At \(T - \Delta t\) the option price \(C(S_{T-\Delta t}, x_{T-\Delta t})\) is clearly bound by the expectations \(E^U\) and \(E^L\) of the payoff, which are convex functions of \(S_{T-\Delta t}\) for any \(x_{T-\Delta t}\), as well as functions of \(x_{T-\Delta t}\). Assume now that at \(t + \Delta t\) the price \(C(S_{t+\Delta t}, x_{t+\Delta t})\) is similarly bound by the expressions \(\tilde{C}(S_{t+\Delta t}, x_{t+\Delta t})\) and \(\underline{C}(S_{t+\Delta t}, x_{t+\Delta t})\) given by (6.5), which are convex in \(S_t Z(x_t)\) for any \(x_{t+\Delta t}\). By the induction hypothesis we have, from (6.4)

\[ e^{-r \Delta t} E[Y_{t+\Delta t} C(S_t Z(x_t), x_{t+\Delta t}) | x_{t+\Delta t}] \leq C(S_t, x_t) \]  

(A.12)

\[ \leq e^{-r \Delta t} E[Y_{t+\Delta t} \bar{C}(S_t Z(x_t), x_{t+\Delta t}) | x_{t+\Delta t}] \]
From (A.12) we get, by the assumed convexity of \( \tilde{C}(S_{t+\Delta t}, x_{t+\Delta t}) \) and \( C(S_{t+\Delta t}, x_{t+\Delta t}) \)

\[
e^{-t\Delta} E\left[E^{U_{t,\omega}}[C(S_t, Z(x_t), x_{t+\Delta t})|x_{t+\Delta}]x_t]\right] \leq C(S_t, x_t) \leq e^{-t\Delta} E\left[E^{U_{t,\omega}}[\tilde{C}(S_t, Z(x_t), x_{t+\Delta t})|x_{t+\Delta}]x_t]\right]
\]

Observe that the expressions within brackets in both sides of this last expression are convex in \( S_t \) for any given \( x_{t+\Delta t} \) since they are expectations of functions of \( S_t, Z(x_t) \) that are convex by the induction hypothesis. Hence, their expectation with respect to \( x_{t+\Delta t} \) is also convex. Hence, \( C(S_t, x_t) \) is bound by the convex expressions in (6.5), QED.
